Alcohol misuse and criminal offending: Findings from a 30-year longitudinal study

Joseph M. Boden, David M. Fergusson and L. John Horwood

Abstract

Background: This study examined the associations between measures of alcohol abuse/dependence (AAD) and several classifications of offending behaviour to age 30 in a New Zealand birth cohort.

Methods: Outcomes included: assault; use of a weapon; theft/burglary/vehicle conversion; property damage/vandalism/arson; and fraud/embezzlement/misappropriation of funds. The study also used measures of AAD symptoms; and time-dynamic covariate factors including life stress, other substance use, mental health status, peer and partner substance use and offending, and unemployment. Data were analysed using conditional fixed effects regression modelling augmented by time-dynamic covariate factors to control for confounding.

Results: Those with five or more AAD symptoms had unadjusted odds of offending that ranged from 6.23 to 21.25 times higher than those with no symptoms, with little evidence to suggest these associations varied with age. Adjustment for both unobserved fixed effects and time-dynamic covariate factors reduced the magnitude of the associations between AAD and offending, with those with five or more AAD symptoms having odds of offending that were 0.88 to 4.10 times higher than those with no symptoms. After adjustment, only the associations between AAD and: a) assault (OR = 4.10; 95% CI = 1.91-8.62; p < .0001); and b) property damage/vandalism/arson (OR = 3.87; 95% CI = 1.30-11.39; p < .0001); remained statistically significant.

Conclusions: The results suggest a causal association between alcohol misuse and “impulsive” crimes such as assault and property damage/vandalism/arson, with estimates suggesting that AAD accounted for approximately 9.6% to 9.9% of these types of reported offending in the cohort.

Keywords: alcohol abuse/dependence, offending, substance use, mental health, longitudinal study
1. Introduction

There has been substantial research into the linkages between the misuse of alcohol and risks of criminal offending (for reviews see: Baumberg, 2006; Bushman and Cooper, 1990; Giesbrecht, 2007; Martin, 2001; Parker, 2004; Rehm et al., 2009; World Health Organization, 2007). In general, this research suggests that the misuse of alcohol has been associated with increased risks of a wide range of offences in many countries (Boden et al., 2012; Bureau of Justice Statistics, 2009; Ensor and Godfrey, 1993; Farke and Anderson, 2007; Fergusson and Horwood, 2000; Gmel and Rehm, 2003; Huckle et al., 2006; Miller et al., 2006; Palk et al., 2007; Scott et al., 1999; Shepherd, 1994; Wood, 2005). While it is now widely accepted that alcohol is a risk factor for crime, there are three general issues that require further investigation and examination.

The first issue concerns the extent to which associations between alcohol misuse and crime reflects a cause and effect association in which the misuse of alcohol lead to an increased risks of crime. Specifically it may be suggested that the apparent linkages between alcohol misuse and crime reflect the personal, social and other characteristics of those who drink heavily rather than the effects of alcohol misuse on the individual’s propensity to offend (Greenland and Morgenstern, 2001; Ward, 2009; Ward and Johnson, 2008). This issue has been addressed in a growing number of studies which have controlled the associations between alcohol misuse and crime using a variety of statistical approaches to adjust for both observed and non-observed sources of confounding (Boden et al., 2012; Fergusson and Horwood, 2000; Fergusson et al., 1996; Flowers et al., 2008; Hingson et al., 2000; Hingson and Zha, 2009; McClelland and Teplin, 2001; Scott et al., 1999). In all cases these studies have reported that associations between alcohol misuse and crime persist following control for various sources of confounding. Of particular note are papers that have used fixed effects regression methods to adjust for non-observed sources of confounding (Boden et al., 2012; Fergusson and Horwood, 2000; Norström and Pape, 2010). These studies suggest that, subject to the availability of longitudinal data it proves possible to develop statistical models of the association between alcohol misuse which take into account fixed sources of confounding including common
genetic and environmental influences that may confound the association between alcohol misuse and crime. The weight of the evidence from fixed effects regression approaches clearly suggests the presence of causal linkages between the misuse of alcohol and rates of crime.

The second issue concerns the effects of age on the associations between alcohol misuse and crime. In particular, it is well-known that rates of both alcohol misuse and crime peak in adolescence and young adulthood (Agnew, 2003; Botvin and Griffin, 2007; Maggs and Schulenberg, 2005; McCarty et al., 2004; Monahan et al., 2009; Steinberg, 2009). It could therefore be suggested that the associations between alcohol and crime are largely or wholly confined to a developmental period spanning adolescence and young adulthood and that this association is reduced or non-existent for older drinkers. Thus to understand the associations between alcohol and crime more fully it is necessary to examine possible age-related changes in this association.

Finally, there is a need for research which takes into account heterogeneity in criminal offending. Many studies in this area have examined the linkages between overall rates of criminal offending without discriminating between different types of offences, or have focussed solely on violent offending. However it may be hypothesised that the contribution of alcohol to crime will vary by the type of offence with those offences involving short-term impulsive actions (e.g. assault; vandalism) being more influenced by alcohol than crimes that require some degree of planning and premeditation (Kallmen and Gustafson, 1998; Parker and Auerhahn, 1998). An earlier study (Welte and Miller, 1987) failed to find strong differences in alcohol use amongst individuals who had been incarcerated for either violent crimes or property crimes, but it could be argued that a simple division between violent and property offending may obscure the possible role of disinhibition in various forms of offending.

Against this background, this paper reports the results of a 30-year longitudinal study of the linkages between the misuse of alcohol and rates of crime in a New Zealand birth cohort studied from birth to the age of 30. The aims of this study were to:
1) Estimate the associations between the misuse of alcohol and rates of offending of different classes, including: assault; use of a weapon; theft/burglary/vehicle conversion; property damage/vandalism/arson; fraud/embezzlement/misappropriation of funds.

2) To adjust associations between alcohol misuse and crime for both observed and non-observed sources of confounding using methods of fixed effects regression.

3) To examine age-related variation in the associations between alcohol misuse and crime.

More generally the aims of this research were to use rich data from a longitudinal study to clarify and elaborate the well-documented associations between alcohol misuse and crime.

2. Methods

2.1 Participants

The data were gathered during the course of the Christchurch Health and Development Study (CHDS). In this study a birth cohort of 1265 children (635 males, 630 females) born in the Christchurch (New Zealand) urban region in mid-1977 has been studied at birth, 4 months, 1 year and annually to age 16 years, and again at ages 18, 21, 25 and 30 years (Fergusson and Horwood, 2001; Fergusson et al., 1989). All study information was collected on the basis of signed consent from study participants and all information is fully confidential. All aspects of the study have been approved by the Canterbury (NZ) Ethics Committee.

2.2 Alcohol abuse/dependence (AAD) symptoms, ages 17-30

In this investigation alcohol misuse has been operationalized as symptoms of alcohol abuse/dependence (AAD). At ages 18, 21, 25 and 30 years, study participants were interviewed concerning alcohol use using components of the Composite International Diagnostic Interview (CIDI)(World Health Organization, 1993) to assess DSM-IV (American Psychiatric Association, 1994)
symptom criteria for AAD. At each point of observation a scale score was constructed based on the number of symptom criteria for AAD that the individual met during the preceding 12-month period, with this score ranging from 0 for those meeting no criteria to a maximum of 11 for those meeting all criteria. Participants were categorized using a four-point scale as to the number of symptoms reported at each age. These categories were: 0, 1-2 symptoms, 3-4 symptoms, or 5+ symptoms.

2.3 Offending outcomes, ages 17-18, 20-21, 24-25, and 25-30

At ages 18, 21, 25, and 30, respondents were questioned about their criminal behaviours since the previous assessment using the Self-Report Delinquency Inventory (SRDI: Elliott and Huizinga, 1989) supplemented by additional custom-written survey items. For the purposes of the present investigation, a number of classifications of types of offending were created using a subset of these questions. This information was used to derive both categorical (yes/no) and count measures of the number of self-reported offenses, across several categories, committed in the year prior to each assessment from age 18 to age 30. The classifications of offences and the items used to create these classifications are described below. For all classifications, participants indicating at least one of these offenses were classified as having committed an offense of that type at that assessment period. In addition, responses to these items were summed to create a count measure of the number of instances of an offense at each assessment period. The classifications included:

2.3.1 Assault. Assault was assessed via responses to three items concerning physical assault and fighting, including: assaulting a person with whom the respondent lived; assaulting a person with the idea of hurting them; and being involved in a gang (group) fight.

2.3.2 Use of a weapon. Use of a weapon was assessed using four items concerning: use of a weapon in a violent assault; using a weapon against someone with whom the respondent lived; aggravated robbery (using a weapon to rob a person or business); or carrying a hidden weapon.
2.3.3 Theft/burglary/vehicle conversion. This category was assessed by several items concerning: petty theft; grand theft (cash or goods over $500); theft from an automobile; breaking and entering; handling stolen goods; shoplifting; burglary; and taking and driving away an automobile without permission.

2.3.4 Property damage/vandalism/arsen. These forms of offending were assessed via two items concerning: destroying or damaging property that did not belong to the respondent (vandalism); and setting fire to a house, building, car or other property.

2.3.5 Fraud/embezzlement/misappropriation of funds. Fraud and related offences were assessed by several items pertaining to: obtaining goods via deception; stealing money from employers or others whom had entrusted the respondent with money; failure to pay bills; and benefit fraud.

2.4 Time-dynamic covariate factors (ages 18-30).

In order to examine the extent to which the associations between alcohol misuse and offending could be explained by factors to which individuals were exposed at a time contemporaneous to both alcohol misuse and offending, the following measures were abstracted from the study database.

2.4.1 History of previous anxiety and depression. These were assessed via items from the CIDI (World Health Organization, 1993), matched against DSM criteria (American Psychiatric Association, 1987, 1994) to derive dichotomous measures of anxiety disorder (of any sub-type) and major depressive disorder for each year. Participants were classified as having had a history of previous anxiety or depression, from that assessment point forward, if they met DSM criteria for anxiety disorder or major depression at any assessment.

2.4.2 Stressful life events. Assessed by responses to items from the Feeling Bad Scale (Lewis et al., 1984) and custom-written survey items. The life events items spanned such areas as
relationship problems and difficulties; serious illness, accident, or death in the family; pregnancy and parenthood; educational or employment difficulties; victimisation; and financial difficulties. Using this information a total life events score was constructed for each year by summing the number of life events reported by the participant in that year.

2.4.3 Cannabis and other illicit drug use. Cannabis use and other illicit drug use were measured by: a) a six-point categorical measure of cannabis use frequency (never to daily) in the twelve months prior to each assessment; and b) a dichotomous (yes/no) measure of whether the individual had used any illicit drugs other than cannabis at any point during the twelve months prior to each assessment period.

2.4.4 Unemployment. Assessed for the 12 months prior to each assessment by asking participants about their experience of unemployment in each period and classified into four levels reflecting the duration of unemployment in the year; never unemployed; < 3 months, 3-5 months; 6+ months.

2.4.5 Peer and partner substance use and offending. Measured for the twelve month period prior to each assessment on the basis of four single items assessing: a) the extent to which the participants’ romantic partners and friends: a) used illicit drugs or had problems resulting from alcohol or illicit drugs, and b) engaged in criminal offending, had problems with aggressive behaviour or were in trouble with the law. The questions assessing peer substance use and offending queried the relative percentage of the individual’s friends who engaged in each of these behaviours (none, some, most).

2.4.6 Conduct/anti-social personality disorder. Measured at age 18 using the Self Report Delinquency Inventory (SRDI: Elliott & Huizinga, 1989). In order to use a more age-appropriate instrument, from age 21 onwards conduct/anti-social personality disorder was assessed using custom-written survey items reflecting the DSM-IV criteria for anti-social personality disorder.
Sample members who met diagnostic criteria for conduct disorder or anti-social personality disorder during an assessment period were classified as having the disorder during that period.

2.5 Statistical analyses

2.5.1 Associations between AAD and offending. In the first stage of the analyses, the pooled association between AAD symptoms and each offending outcome was estimated via Generalized Estimating Equation methods (Liang and Zeger, 1986; Zeger and Liang, 1986) to fit a population-averaged logistic regression model in which the risk of each outcome each time period was modelled as a function of AAD symptoms during each time period. These models were of the form:

\[ f(Y_{it}) = B_0 + B_1 X_{it} \]  

(EQ1)

where \( f(Y_{it}) \) was the log odds of each offending outcome reported by the ith subject in a given interval t (t = 17-18 years; 20-21 years; 24-25 years; and 29-30 years), and \( X_{it} \) represented AAD symptoms during the interval t. In this model observations from the same individual over time were permitted to be correlated with an unstructured correlation matrix. From the fitted models, estimates of the odds ratio (OR) and 95% confidence intervals (CI) of AAD symptoms for violence outcomes were calculated. In addition, these models were extended to include terms representing: a) time; and b) a time period x AAD symptoms interaction, in order to account for the possibility that rates of AAD symptoms varied over time.

2.5.2 Fixed effects model for covariate adjustment. To adjust the associations between AAD symptoms and violence outcomes for both: a) non-observed fixed effects; and b) observed time-dynamic confounding factors, conditional fixed effects regression models were fitted to the joint data for each of the four outcomes over the measurement periods. These models were of the form:

\[ f(Y_{it}) = \alpha_i + B_1 X_{it} + \sum B_k Z_{ikt} \]  

(EQ2)
In this model $\alpha_i$ are individual specific terms that are assumed to reflect the effects of all fixed sources of variation in the outcome $Y_{it}$. The fixed effects $\alpha_i$ are assumed to be constant over time and to be correlated with other predictors in the model. The models were also augmented by the terms $Z_{it}$, representing the set of observed time-dynamic covariates.

In addition, the analyses above were repeated using a count measure of the number of offences in place of the dichotomous measure at each age, with negative binomial regression models used in place of logistic regression. In all cases the count measures of offending outcomes were truncated to a maximum of 50 offences per individual in order to avoid the undue influence of extreme outliers.

Finally, estimates of the population attributable risk (PAR) for each offending outcome that remained statistically significant after adjustment were calculated using methods described by Bruzzi et al (Bruzzi et al., 1985), after adjustment for both non-observed fixed effects and time-dynamic covariate factors.

2.6 Sample sizes

The present analyses were based on samples ranging from 987 to 1025, representing 78% to 81% of the original cohort of 1265 participants, for whom data were available concerning AAD and offending outcomes at ages 18, 21, 25, and 30. To examine the effects of sample losses on the representativeness of the sample, the obtained samples with complete data at each age, were compared with the remaining sample members on a series of socio-demographic measures collected at birth. This analysis suggested that there were statistically significant ($p<.01$) tendencies for the obtained samples to under-represent individuals from socially disadvantaged backgrounds characterized by low parental education, low socio-economic status and single parenthood. To address this issue, the data weighting methods described by Carlin et al. (1999) were used to examine the possible implications of selection effects arising from the pattern of missing data. These
analyses produced essentially the same pattern of results to those reported here, suggesting that
the conclusions of this study were unlikely to have been influenced by selection bias.

3. Results

3.1 Associations between symptoms of AAD and offending categories, ages 18-30.

Table 1 shows the associations between AAD and a series of five self-reported offending categories
at ages 17-18, 20-21, 24-24, and 29-30. For each category of offending, the percentage reporting at
least one instance of that crime for each level of AAD symptoms (0, 1-2, 3-4, 5+) during the 12
months prior to each assessment period is shown. The Table also shows estimates of the
population-averaged odds ratio (OR) and 95% confidence interval (CI) for the pooled association
between AAD symptoms and each category of offending, derived from generalized estimating
equation (GEE) logistic regression models (see Methods). In addition, the Table reports on tests of
age x AAD symptoms interactions derived from the GEE models. The Table shows:

1. There were statistically significant associations (p < .0001) between AAD symptoms and each
category of self-reported offending, with those reporting higher levels of AAD symptoms having
significantly increased odds of reporting offending. Those with five or more symptoms of AAD
had odds of offending that ranged from 6.23 times to 21.25 times higher than those reporting no
symptoms.

2. Examination of the overall rates of offending categories show that rates of offending decreased
as age increased. The main effect for age was statistically significant (p < .0001) for all five of the
offending categorizations.

3. For one outcome (theft/burglary/vehicle conversion) there was evidence of a statistically
significant (p < .05) age x AAD symptoms interaction, and there was one marginally significant (p
< .10) age x AAD symptoms interaction (use of a weapon). In both cases, the age x AAD
symptoms interaction term was used in all subsequent analyses. In all other cases, there was no
evidence of statistically significant age x AAD symptoms interactions, suggesting that for those outcomes the strength of association between AAD symptoms and outcomes did not vary by age.

4. In addition, there were also trends for rates of AAD symptoms to decline with age (p < .0001).

3.2 Associations between AAD symptoms and offending outcomes, adjusted for a) non-observed confounding factors; and b) time-dynamic covariate factors.

In order to examine the extent to which the associations between AAD symptoms and offending outcomes could be explained by the influence of: a) sources of non-observed fixed confounding; and b) time-dynamic covariate factors occurring contemporaneously with AAD symptoms and offending outcomes, the analyses depicted in Table 1 were extended over by fitting conditional fixed effects logistic regression models to the data, augmented by a series of observed time-dynamic covariate factors measured contemporaneously with both AAD symptoms and offending outcomes (see Methods). The observed time-dynamic factors reflected each individual’s exposure to: stressful life events, associating with deviant peers and partners, and substance use and mental health issues that may have influenced the observed bivariate associations between AAD symptoms and offending outcomes. The results of these analyses are shown in Table 2, which shows the adjusted ORs and 95% CIs for the associations between AAD symptoms and each offending outcome, after adjustment for: a) non-observed sources of confounding; and b) time-dynamic covariate factors. The Table shows:

1. Adjustment for non-observed confounding and time-dynamic covariate factors reduced the magnitude of the associations between AAD symptoms and offending outcomes. After adjustment, the associations between AAD symptoms and: a) use of a weapon; b) theft/burglary/vehicle conversion; and c) fraud/embezzlement/misappropriation of funds; were reduced to statistical non-significance (all p values > .05).
2. Although adjustment for fixed effects and time-dynamic covariate factors reduced the magnitude of the association between AAD symptoms and: a) assault; and b) property damage/vandalism/arson; the associations remained statistically significant (p < .05). After adjustment, those having five or more symptoms of AAD having odds of offending that ranged from 3.87 to 4.10 times higher than those with no symptoms of AAD.

In general, the results of the analyses suggest that the linkages between alcohol misuse and offending outcomes varied depending upon the nature of the offence in question. For those offences that may be related to impulsive behaviour (assault, property damage/vandalism/arson), the findings suggest that alcohol misuse was related to increased risks of these outcomes, even after controlling for possible confounding. However, the analyses suggest that the observed linkages between alcohol misuse and other forms of offending that may appear to require more planning and coordination (use of a weapon; theft/burglary/vehicle conversion; fraud/embezzlement/misappropriation of funds) were largely explained by a range of sources of potential confounding.

3.3 Population attributable risk (PAR)

As noted in Methods, estimates of the PAR for the role of AAD in the outcomes that remained statistically significant after adjustment (assault; property damage) were calculated using methods described by Bruzzi et al (Bruzzi et al., 1985), after adjustment for fixed effects and time-dynamic confounding factors. These analyses showed that 9.9% of assault and 9.6% of property damage/vandalism/arson could be accounted for by the presence of AAD.

INSERT TABLE 2 HERE
3.4 Supplementary analyses

As described in Methods, the analyses reported above were repeated using count measures of the number of offending in each category, in place of the dichotomous measure of the percentage reporting each crime category at each age period. Repeated measures negative binomial GEE models were used to model the associations between AAD symptoms and the count measures of offending categories, and to adjust the associations for both non-observed confounding and time-dynamic covariate factors. In all cases the results of these analyses were congruent with those reported above, suggesting that the use of count measures in place of percentage measures did not materially alter the conclusions drawn by the study.

4. Discussion

This study has used data gathered over a 30-year longitudinal study to examine the linkages between alcohol misuse, as measured by AAD symptoms, and rates of crime over the period from ages 17–30. The key findings and their implications are summarised below.

First, consistent with previous studies examining the linkages between alcohol misuse and crime (Bureau of Justice Statistics, 2009; Farke and Anderson, 2007; Gmel and Rehm, 2003; Huckle et al., 2006; Palk et al., 2007; Scott et al., 1999), this study produced evidence of bivariate statistical associations between the extent of alcohol misuse and all types of crime at all ages. In general, increasing rates of AAD symptoms were associated with increased risks of: assault; use of a weapon; theft/burglary/vehicle conversion; property damage/vandalism/arson; and fraud/embezzlement/misappropriation of funds. Compared to those with no symptoms of AAD, those with five or more symptoms had odds of crime that were 6 to 21 times higher. Further, these associations remained relatively stable over the period from 17 to 30 years, and in only one case was there evidence of a statistically significant age x AAD symptoms interaction. On the basis of this there is little doubt that there were strong associations between the misuse of alcohol and all types
of crime with these associations being evident up to the age of 30. However, the study findings also showed that both rates of offending and rates of AAD symptoms declined with age. The net effects of these age-related changes was that while the relationships between alcohol misuse and crime were evident at all ages, the number of alcohol-related crimes declined with age.

Further analyses of the associations between offending and AAD showed that much of this apparent association was spurious and explained by common confounding factors that were associated with both alcohol misuse and crime. Specifically control for common fixed effects and time-dynamic sources of confounding reduced the ORs for those with five or more AAD symptoms to between to 0.88 to 4.10. After control for all factors, the misuse of alcohol was associated with only two outcomes: assault (AOR = 4.10; 95%CI: 1.91-8.62; PAR = 9.9%); and property damage/vandalism/arson (AOR = 3.87; 95%CI: 1.30-11.39; PAR = 9.6%). These findings are consistent with the conjecture made in the Introduction that the effects of alcohol misuse are most likely to be associated with crimes involving impulsive behaviours, and least likely to be involved in crimes requiring planning and forethought. It is also interesting to note that the present study suggests that much of the association between AAD and crime is spurious and arises from common factors that are associated with both AAD and crime (Greenland and Morgenstern, 2001; Ward, 2009; Ward and Johnson, 2008). These factors may include both common genes that influence the propensity to alcohol misuse and crime (Holmes et al., 2001; Osby et al., 2010; Tuvblad et al., 2006; Whitfield et al., 2004) and common environmental factors (e.g. peer affiliations) that are associated with both outcomes (Fergusson et al., 1996; Widom and White, 1997).

While these findings provide some confirmation of previous research into alcohol misuse and crime, there is one limitation of the research that needs to be recognised. Specifically, the ways in which alcohol misuse has been measured in this research means that the association being studied is the relationship between the individual’s propensity to alcohol abuse and their propensity to crime. What this research does not examine is the role of alcohol misuse in specific instances of crimes committed by those cohort members whose drinking was generally non-problematic but who
may have committed a crime whilst under the influence of alcohol. The ways in which the AAD symptoms were gathered meant that individuals who were generally non-problematic drinkers but who may have engaged in instances of criminal activity as a result of heavy drinking would have been coded as having low levels of AAD symptomatology. For these reasons the present study is likely to under-estimate the effects of alcohol misuse on crime.

Nonetheless within these limitations the study findings suggest that the increasing misuse of alcohol was associated with increasing risk of crimes involving impulsive acts including assault, property damage, vandalism and arson. These increased risks were evident up to the age of 30, suggesting that the linkages between alcohol misuse and crime were robust to changes in levels of alcohol consumption and involvement in criminal behaviour over the lifespan.
